

Circulation in Animals

- It is the movement of body fluids inside the body of animals so as to transport materials from the region of formation to the region of utilization or disposal. A circulatory system is a complex of structures involved in the flow of body fluids of an organism so as to accomplish transport of materials
- Circulation of body fluids can be of the following types
 1. Intracellular circulation It occurs inside the individual cells through cyclosis or cytoplasmic streaming.
Examples : Paramecium, Amoeba.
 2. Extracellular circulation In multi-cellular animals, the living cells are bathed in an intercellular or extra cellular fluid which circulates in the body for transport of materials Extra cellular circulation can be
 - a) Extra-organismic circulation: Outside water circulates in the body of an organism
 - b) Intra-organismic circulation: It involves circulation of body fluid
 - i) Parenchymal circulation In flatworms, fluid filled spaces present in parenchyma tissue between body wall and internal organs are used in distribution of substances.
 - ii) Coelomic Circulation Coelomic fluid is employed in transport of substances,. Pseudocoelom is used for this purpose in roundworms. Haemocoel does so in arthropods
 - iii) Blood vascular system It contains blood and a pumping structure (heart) for circulation of materials inside the body. Lymphatic system accompanies blood vascular system.

FUNCTIONS OF CIRCULATORY SYSTEM

- 1) Transport of nutrients
- 2) Transport of waste products.
- 3) Transport of respiratory gases
- 4) Transport of metabolic intermediates like lactic acid from muscles to liver
- 5) Transport of hormones.
- 6) Regulation of pH by means of buffer.
- 7) Regulation of temperature.
- 8) Distribution of water.
- 9) Support or turgidity of certain organs like penis and nipples
- 10) Prevention of diseases by means of antibodies and antitoxin present in it
- 11) Disposal of cell wreckage.
- 12) Homeostatis or providing a stable internal environment for cells
- 13) Determination of pigmentation in case of blood vascular system.
- 14) Plugging the area of injury.
- 15) As connective tissue

OPEN CIRCULATORY SYSTEM

- Open circulation occurs in arthropods and mollusks.
- The blood is not completely enclosed within vessels, the heart pumps blood through arteries into large cavities or sinuses, where it mixes with interstitial fluid and bathes the cells of the body.
- Blood is a combination of blood and interstitial fluid called haemolymph, while the spaces and lacunae are together called haemocoel.
- The blood is slowly returned to the heart through small pores called ostia e.g. arthropods (cockroach)
- Circulation is slower in an open system, because with some of the blood pooled in sinuses, the heart cannot build up enough pressure to make blood flow rapidly.
- Open system cannot achieve the high rates of oxygen transport that active animals require.
- Animals with open systems are either small and sluggish or use open system only for transport of food and wastes and use a different system for the transport of gases.
- Respiratory pigment, if present, is dissolved in the plasma, no red corpuscles are present.

CLOSED CIRCULATORY SYSTEM

- Closed circulatory system is a type of blood vascular system in which blood remains confined and flows inside blood vessels only, never coming in direct contact with body cells. It occurs in most annelids, cephalopods and vertebrates. Annelids are the simplest animals to have closed circulatory system.
- Flow of blood is Heart → artery → arteriole → capillary → venule → vein → heart
- Circulatory system as discovered by William Harvey (1628), blood capillaries by Malpighi (1661) blood pressure by Haller (1732) and sphygmomanometer by Riva Rocci (1896)

HEART

- In prawn, heart is arterial as it pumps only oxygenated blood. Vertebrate heart shows evolutionary development.
- Sinus venosus is a distinct sac which is specialized to receive venous blood. It opens into auricle.
- Conus/ truncus arteriosus is another similar sac into which ventricle opens for distribution of arterial blood.
- In fishes, heart is two chambered with an auricle / atrium and a ventricle. Both sinus venosus and conus arteriosus are present. There is a single circulation and heart pumps only venous (deoxygenated) blood to gills from where it passes to different body parts. Heart of fishes is therefore venous or branchial
- Arteriovenous heart occurs in lungs fishes amphibians, reptiles, birds and mammals because it receives both venous (deoxygenated and arterial (oxygenated) blood). There is double circulation, pulmonary (to and from lungs) and systematic (to and from other body parts)

- In amphibians there are two auricles/ atria.
- In amphibians there are two auricles/ atria, one ventricle, a sinus venosus and conus/ truncus arteriosus. Mixing of oxygenated and deoxygenated bloods occur in ventricle.
- In reptiles, the heart has two atria and an incompletely divided ventricle. Sinus venosus is present but conus arteriosus has merged with ventricle and aorta.
- In crocodiles, the ventricle is almost completely divided through mixing of bloods does occur
- Heart is completely four-chambered in mammals and birds with neither sinus venosus nor conus arteriosus. There are two atria and two ventricles. The left part of the heart is connected with oxygenated blood (scarlet red) and right part with deoxygenated blood (purple red)

ARTERY

- It is a blood vessel that carries blood away from the heart towards an organ. Artery generally contains oxygenated blood (deoxygenated in pulmonary artery). The blood flows in an artery under alternate increased pressure and with jerks. Arteries are deep seated with thick elastic wall and comparatively narrow lumen. They become empty after death. Valves are absent. The wall is made up of three regions tunica externa, tunica media or tunica adventitia is outer coat made of loose connective tissue with abundant white (collagen) and fewer yellow (elastin) fibres as well as longitudinal smooth or unstriated muscle fibres. There is a well developed external elastic lamina on the inner side. The middle coat or tunica media is thick having unstriated circular muscles and elastic connective tissue. The inner coat, tunica interna or tunica intima is also made of connective tissue. It has a number of folds. The lumen is lined by an endothelium of elongated flat thin squamous tissue. There is an elastic membrane of yellow fibers called internal elastic membrane or lamina.

VEINS

It is a blood vessel that carries blood from an organ towards the heart. Vein generally contains deoxygenated blood (oxygenated in pulmonary veins). Flow of blood is smooth, without jerks and under little pressure intervals, a vein contains semilunar valves to maintain blood flow in one direction. Each semilunar valve has two cusps, rarely three or one Venous flow of blood is maintained by milking action of surrounding muscles, contraction of diaphragm and other body movements. Veins are mostly superficial with thin wall and wide lumen. After death a vein retains blood. Structurally, the wall of vein has the same three parts as in an artery, tunica externa, tunica media and tunica interna. Tunica externa is the outer coat with loose connective tissue, abundant white and fewer yellow fibres. It is well developed but external elastic lamina is not much differentiated. Tunica media is comparatively thinner in vein with a few smooth circular muscles. Tunica interna is similar to the artery but with fewer folds, less developed internal elastic membrane and less elongated endothelial tissues. Semilunar valves are made of folds of endothelium with some enclosed connective tissue.

CAPILLARY

- It is a very fine blood vessel where the wall is made of a single layer of endothelium of tasseled cells. Fine intercellular cleft occur between the adjacent endothelial cells. Basement membrane lies on the outside. Blood capillaries are formed by arterioles. They join to produce venules. The lumen of blood capillary is so fine that red blood corpuscles can pass through it in a single file. The WBC can come out of them through the process of diapedesis. Because of their extremely thin walls, blood capillaries take part in exchange of materials between blood and tissue fluid. In lungs, they pick up oxygen and give out CO₂ through diffusion. All the blood capillaries are not functional all the time. Some of them work only at the time of intense activity. Their working is controlled by precapillary sphincters present in the area of their origin.

ARTERIO-VEINUS ANASTOMOSIS

It is a direct vascular connection between an arteriole and venule bypassing capillary supply. The connection occurs in certain exposed parts like finger tips, nose, pinnae, eye lids, lips, tongue etc. It is meant for controlling blood supply and temperature of the exposed parts.

VASCULAR PLEXUS

Anastomosis of blood vessels is like arteries in certain regions to provide extra blood e.g. cutaneous plexus, papillary plexus, nasal plexus.

EFFICIENCY OF CLOSED RESPIRATORY SYSTEM

- i) It can regulate blood flow into an organ.
- ii) Blood flows rapidly in blood vessels than in open spaces
- iii) There is quick supply and removal of materials.
- iv) Blood flows to all parts of the body with equal efficiency and speed.

BLOOD

It is complex mobile fluid connective tissue of reddish colour in which the fluid matrix is not synthesized by the contained cells. An adult human has 5-5.5 litres of blood. Ph is 7.4. Blood consists of two parts, plasma and blood corpuscles (formed elements)

PLASMA

- It is slightly alkaline non-living intercellular substance which constitutes about 60% part of the blood. It is a pale yellow but transparent and clear fluid.
- It is composed of 91-92% of water, 7% proteins, 0.9% inorganic substances, 0.1% glucose and traces of other constituents (amino acids, fatty acid, fat drops, cholesterol, anticoagulants, hormones, excretory products, vitamins etc.)

- The main categories of protein are albumins, globulins and fibrinogen. Albumins produce colloidal osmotic pressure. It also carry ca and some fatty acid α -globulin, β -globulin carry fat soluble vitamins, cholesterol and ions other globulin are prothrombin, thromoplastin and anti haemophilic factors. Fibrinogen takes part in blood coagulation by forming fibrin
- Mineral salts like chlorides, bicarbonates, sulphates and phosphate of sodium, potassium calcium, iron and magnesium constitute about 0.9% of plasma. Buffer of the blood is sodium bicarbonates

FUNCTION OF BLOOD PLASMA

- i. Transport
- ii. Retention of fluid in blood.
- iii. Maintenance of blood pH
- iv. Body immunity
- v. Prevention of blood loss
- vi. Conducting heat to skin for dissipation
- vii. Uniform distribution of heat all over body

BLOOD GLUCOSE

- Usually blood glucose level is about 80-100 mg per 100 ml of blood 12 hours after a normal meal
- If blood glucose level exceeds 180 mg per 100 ml, it starts appearing in urine. This condition is called glucosuria. If it is less it causes hypoglycemia and if it is higher it causes hyperglycemia.

BLOOD CHOLESTEROL

Its normal amount is 80-180 mg in 100 ml of blood plasma. Increased blood cholesterol may lead to its deposition in the internal wall of the blood vessels like arteries and veins which causes high blood pressure and heart problem

FORMED ELEMENTS

Erythrocytes (Red blood corpuscles or RBCs)

- A normal adult man and woman have 5 to 4.5 million RBCs per cubic millimeter of blood respectively.
- Less amount of haemoglobin leads to anemia which may be caused by loss of blood or destruction of RBCs.
- An abnormal rise in RBC count is called polycythemia. Decrease in the number of RBC count is called erythrocytopenia which causes shortage in the blood and tissues
- They are biconcave, disc-shaped enucleate reddish coloured cells of 7-8 μ m in diameter and 1-2 μ m thick. Red colour is due to the presence of haemoglobin
- Haemoglobin is a conjugate protein which is made up of a protein called globin and a non protein group heme (=haeme) hence the haemoglobin.

- Haemoglobin is oxygen carrying pigment. 100ml of blood of a normal man contains 15g of haemoglobin and of normal woman an average of 13g of haemoglobin
- Erythropoiesis is the process by which red blood cells are produced. In human adults, this usually occurs within the bone marrow.
- The life of an RBC is about 120 days. The worn out RBCs are destroyed in the spleen and liver
- Their iron is returned to the red bone marrow for reuse in the synthesis of fresh haemoglobin
- Their pigment is degraded to yellowish pigment bilirubin which is excreted in bile.

ERYTHROCYTE SEDIMENTATION RATE (ESR)

If blood containing an anticoagulant (oxalate) is allowed to stand in a narrow vertical tube the erythrocyte settle to the bottom half of the tube. The rate at which this occurs is called the erythrocyte sedimentation rate. ESR is very useful in diagnosing various diseases including tuberculosis. ESR in men is 0-5 mm/hr and in women it is 0-7mm/ hour.

- Leucocytes (White blood corpuscles or WBCs)
 - They are colourless, active and mobile nucleated blood corpuscles with a number $7000 \pm 3500 / \text{mm}^3$. Leucytes are of two types granulocytes (with granules and polymorphic nucleus) and agranulocytes (without granules and monomorphic nucleus).
 - The life of granulocytes is normally 40 to 8 hours circulating in the blood and another 4-5 days in the tissue
 - Monocytes have a short life span of 10-20 hours. The lymphocytes have life span of few days or months or years
 - Granulocytes are of three types (neutrophils, basophils, eosinophils) while agranulocytes are of two types (monocytes and lymphocytes)
- Neutrophil
They have granules that stain with neutral dyes nucleus 2-7 lobed, nearly circular, 62% of all leucocytes, phagocytic.
- Eosinophile
Coarse granules that get stained with acidic dyes (bright red with eosin), nucleus bilobed, size 10-14 μm , 2-3% of total leucocytes, number increases in asthma.
- Basophil
Fewer coarse granules stained with basic dye (methylene blue), nucleus S shaped and 3 lobed, 0.5% - 1%, allergic reactions by releasing histamine, also heparin and serotonin.
- Lymphocytes: Large nucleus with granule free pale blue cytoplasm, 30% of total leucocytes, manufacture globins some of which function as antibodies in immunological reactions. Lymphocytes have size of 7-10 μm , nucleus stains more deeply with basic dyes than surrounding cytoplasm. Large lymphocytes have 10- 14 μm , nucleus stains more deeply with basic dyes than surrounding cytoplasm. Large lymphocytes have 10-14 μm and more cytoplasm. On basis of site of maturation, two kinds β -lymphocytes and T-lymphocytes

Monocytes

Largest leucocytes, 10-18 μm kidney shaped nucleus, 5-6% of total leucocytes motile, phagocytic, scavengers, production of interleukin and pyrogen.

THROMBOCYTES (BLOOD PLATELETS)

- There are about 250,000 platelets in a cubic millimeters of blood. Increase and decrease in the number of platelets is known as thrombocytosis and thrombocytopenia respectively.
- They are rounded or oval disc like bodies platelets are 2-3 μm in diameter. They are colourless
- Platelets are formed from the megakaryocytes (very large cells of the bone marrow). Formation of thrombocytes is called thrombopoiesis.
- Normal life span of blood platelets is about a week
- When an injury is caused, the blood platelets release certain chemicals which are called the platelet factors (thromboplastin). The platelet factors help in the clotting of blood

BLOOD COAGULATION (BLOOD CLOTTING)

When an injury is caused to a blood vessel, bleeding starts which is topped by a process called blood clotting or blood coagulation

- First step: At the site of an injury, the blood platelets disintegrate and release a phospholipid called platelet factor-3 (Thromboplastin). Injured tissues also release a lipoprotein factor called thromboplastin. These two factors combine with calcium ions Ca^{+2} and certain protein of the blood to form an enzyme called pro-thrombinase.
- Second step: The prothrombinase inactivates heparin in the presence of calcium. Prothrombinase catalyzes breakdown of prothrombin into an active protein called thrombin and some small, peptide fragments.
- Third step: Thrombin acts as enzyme and first brings about depolymerization of these monomers. Later thrombin stimulates repolymerization of these monomers into long insoluble fibres – like polymers called fibrin. The thin, long and solid fibres of fibrin form a dense network upon the wound and trap blood corpuscles to form a clot. The clot seals the wound and stops bleeding. Soon after the clot seals the wound and stops bleeding. Soon after the clot starts contracting and a pale yellow fluid, the serum, starts oozing out. This serum is blood plasma minus fibrinogen and blood corpuscles. Vitamin K is essential for blood clotting as it is necessary for the synthesis of prothrombin in the liver

FUNCTIONS OF BLOOD

- i) Transport of food materials : Blood transports the digested food from the alimentary canal to the different body cells
- ii) Transport of respiratory gases : Oxygen is carried from the respiratory organs to the tissues and carbon dioxide from the tissue to the respiratory organ by blood.
- iii) Transport of hormones: Hormones are carried by blood from the endocrine glands to the places of use

- iv) Transport of excretory matter: Blood transport the excretory matter to the kidney or other excretory organs.
- v) Transport of heat: Blood allows the transfer of heat from the deeper tissue to surface of the body where it can be lost.
- vi) Defense against infection: Some white blood corpuscles are phagocytic in action, however, certain blood corpuscles produce antitoxins to neutralize the toxins released by the foreign germs.
- vii) Temperature regulation : Blood maintains the body temperature to a constant level after distributing heat within the body.
- viii) Water balance: Blood maintains water to a constant level by bringing about constant exchange of water between circulating blood and the tissue fluid
- ix) Maintenance of pH: Blood helps to regulate the pH of the body.
- x) Prevention of excessive loss of blood: When any part of the body is injured, loss of blood is prevented by the formation of a clot.
- xi) Helps in healing: Blood maintains necessary supplies for the repair of damaged tissue. Eosinophils and basophils help in the healing of wound.
- xii) Maintenance of physiological co-operation: Blood maintains a physiological cooperation between parts of the body by circulating from one to other parts.

BLOOD GROUP

- Karl Landsteiner reported first time ABO blood groups in human being (1900). AB blood group was found out by de castellan and Steini (1902)
- If a blood transfusion is made between an incompatible donor and recipient, reaction of antigen on the cells and antibodies in the plasma produce clots that clog capillaries.

Blood Group	Genotype	Antigens In RBC	Antibodies in blood plasma	Receive blood	Donate blood	Percentage Humans
A	$I^A I^A$ or $I^A I^O$	A	b	A, O	A, AB	41%
B	$I^B I^B$ or $I^B I^O$	B	a	B, O	B, AB	10%
AB	$I^A I^B$	AB	None	O, A, B, AB (Universal Recipient)	AB	4%
O	$I^O I^O$	None	a, b	O	O, A, B, AB (Universal Donor)	45%

Rh (Rhesus) blood group

- A protein named Rhesus antigen is present on the surface of red blood corpuscles in many persons. It was discovered in 1940 by Landsteiner and Wiener in the blood of Rhesus monkey, hence its name
- 85% of humans (93% Indians) have blood protein called Rh factor (Rh^+). Other without the factor are called Rh^-
- Rh is tested with the help of Rh antiserum or plasma containing Rh antibodies. Agglutination occurs in Rh^+ cases while nonagglutination shows Rh^- nature. Rh^+ is dominant over Rh^- . The antigen formation is determined by a dominant allele R. It gives rise to Rh^+ condition. Presence of double recessive, rr, does not form antigen so that the individual is Rh^-
- Rh^+ blood given to Rh^- person produces an anti-Rh factor 'a'. the first baby is safe due to late development of anti-Rh factor 'a'.
- However, the second Rh^+ baby will either die in foetus stage or born anaemic with several abnormalities due to disintegration of red blood cells (erythroblastosis foetalis) by anti-Rh factor 'a' (anti-Rh globulin is available to overcome the defect) and consequent production of excess bilirubin. The latter can damage the brain of the infant. However, it can damage the brain of the infant. However, the reverse does not have the effect. Oswald Hope Robertson is the creator of the first blood bank.

IMPORTANCE OF BLOOD GROUPS

- i) Knowledge of blood group is essential for blood transfusion
 - ii) Rh compatibility is required for both marriage and transfusion in order to prevent erythroblastosis
 - iii) Preliminary information about disputed parentage and progeny is provided by blood grouping.
 - iv) Blood grouping is used in forensic identification of blood stains.
- Human Heart**
- It is a reddish conical muscular mesodermal hollow organ of a about 12cm length 9 cm breadth, weighs about 300gm and lies behind the sternum in the mediastinum space of thoracic cavity in between the two lungs. Broader base is upwards.
 - The mammalian heart comprises of four complete chambers two ventricles and two auricles (atria)
 - Heart wall consists of connective tissue, blood vessels and cardiac muscle fibres. The latter form a cross – connected network for smooth passage of constriction wave. The cardiac muscle or myocardium does not tire due to
 - a) Alternate rest and activity
 - b) Non- formation of lactic acid
 - Heart is covered by a double fibrous sac or pericardium. It has two components outer non-distensible tough fibrous pericardium (prevents excessive expansion of heart) and inner thin serous pericardium.
 - Serous pericardium has two thin secretory membranes, outer parietal and inner visceral. It encloses a narrow pericardial cavity having pericardial fluid for frictionless movement, protection from shock and mechanical injury

- There is a depression or coronary sulcus between atria and ventricles, interatrial sulcus (two parts, anterior and posterior) between two ventricles. Coronary arteries are housed in these sulci. They supply blood to walls of heart.
- Atrial appendages is protruded part of atria which overhangs the ventricles. Low ridges occur internally in the region of atrial appendage. They are called muscoli pectinati. Blood vessels connected to heart are known as great blood vessels
- Deoxygenated blood flows through right half of heart and oxygenated blood flows through left half of heart. The right and left atria are separated by inter atrial septum. It bears a depression called fossa ovalis (in the area of foetal opening called foramen ovale). Right atrium / auricle receives deoxygenated blood from superior vena cava (upper part of body), inferior vena cava (middle and lower part of body) and coronary sinus (heart walls). The basius valve occurs at the opening of coronary sinus and Eustachian valve at the opening of inferior vena cava
- Back flow in superior vena cava is prevented by obliquity of opening. The left atrium / auricle receives oxygenated blood from two lungs through four pulmonary veins. Right and left ventricles are separated by an interventricular septum
- Left ventricle is larger, includes the apex part and has extra thick wall as compared to right ventricle due to its mechanical requirement of pumping oxygenated blood to all parts of body, walls of ventricle posses a network of low ridges or columnal carnea and a few large muscular projection or papillary muscles/musculi papillares.
- Right ventricle contains a moderator band that extends between upper papillary muscle and inter-ventricular septum. Atria opens into ventricles through atrio-ventricular apertures is guarded by valves. Right atrioventricular aperture is guarded by tricuspid valve possessing three flaps and left atrio-ventricular aperture is guarded by bicuspid and mitral valve possessing two flaps.
- The flaps of the valves are held in their position by fine inelastic cords or chordae tendineae connected to papillary muscles. Left ventricle opens into aorta. The opening is guarded by an aortic semilunar valve between two.

CONDUCTION OF HEART BEAT

- The automatic rhythmicity of the heart is its ability to contract spontaneously at a regular rate
- In practice this represents apex or ventricular beat with an advantage of 72/minutes in adult human. It is high in infants and low in aged persons. Similar heart beat is fast in small animals (200/min in Rabbit and 500/min in sparrow) and low in large animals (25 /min in elephant) as well as cold blooded animals (64/min in frog).
- The heart beat is of two types: Neurogenic and myogenic. The neurogenic heart beat is initiated by a nerve impulse coming from a nerve by a nerve impulse coming from a nerve ganglion (mass of nerve cells, situated near the heart. It is present in the heart of some annelids and most arthropods. The myogenic heart beat is initiated by a path of modified heart muscle itself. It is found in hearts of mollusks and vertebrates.
- In the myogenic heart beat, contraction is initiated by a specialized path of modified heart muscles, the sinoatrial node (SA node) which is situated in the wall of the right auricle near the opening of superior vena cava.
- The SA node acts as the pacemaker' of the heart because it is capable of initiating impulses which then can stimulate the heart muscles to contract. It thus establishes the basic rhythm at which the heart beats
- The impulse of contraction emitted by the sinoatrial node spreads as a wave of contraction over the right and left atrial wall pushing the blood through the strio ventricular valves into the ventricles.
- This wave of contraction next reaches the atrio-ventricular (AV – node) or pacesetler. Which is stinulated to emit an impulse of contraction spreading to the ventricular muscle in the atrioventricular bundle and the purkinje fibres.

- The atrial muscle fibres are separated from those of the ventricles by a fibrous tissue ring. There is no functional continuity between the atria and ventricles. The only conducting tissue between the atria and the ventricles is the atrioventricular bundle or the Bundle of His).
- The atrioventricular bundle (Bundle of His) was discovered by His (1893) and consists of a set of specialized muscle strands originating from AV node and pass downwards into the inter-ventricular septum. This bundle then divided into the left and right bundle branches, one going to each ventricle.
- Within the myocardium of the ventricles the branches break up into a network of fine branching, anastomosing filaments of fibres known as Purkinje fibres.
- The bundle of His and the Purkinje fibres convey the impulse of contraction from the AV node to the myocardium of Ventricles.

PACE-MAKER

- SA node is called natural pace maker of heart as impulse generated by it spreads to both atria and through AV node to ventricles for their rhythmic contraction.
- Disruption or insufficiency of any component of this impulse conducting system results in slowing down or irregularity of heart rhythm or independent contraction of atria and ventricles. Failure of atrial impulse to pass into ventricles for a few seconds to few hours is called ventricular escape or stokes- Adam syndrome. In all such cases an artificial pace – maker is implanted.

- It is an electric device first developed by Greatbatch and Chardack (1960) which is connected to heart for covering up any deficiency of myogenic functioning so as to make it beat normally (72-80/ min) A pacemaker has a pulse generator having long lasting lithium halide cells (with over 10 years of life) and a biocompatible plastic covered fine metallic string for functioning as muscles stimulating electrode. There are various types of pacemaker.
 - i) External pacemaker
 - ii) Epicardial pacemaker
 - iii) Endocardial pacemaker
 - iv) Demand pacemaker
 - v) Atrial synchronized
 - vi) Temporary pacemaker
 - vii) Permanent pacemaker
- In common type, the pulse generator is placed below skin under right clavicle while the string / cable is passed via superior vena cava right atrium and allowed to rest against the tip of right ventricle.
- Pacemaker are liable to be influenced by microwave ovens, metal detectors, electric shavers cellphone etc.

CARDIAC CYCLE

- The cardiac cycle consists of one heart or one cycle of contraction and relaxation of the cardiac muscle. The contraction phase is called the systole while the relaxation phase is called diastole.
- When both the atria and ventricles are in diastolic or relaxed phase, this is referred to as a joint diastole. During this phase, the blood flows from the superior vena cava and inferior vena cava into the atria and from atria to the respective ventricles through auriculo ventricular valves. But there is no flow of blood from ventricles to the aorta and pulmonary trunk as the semilunar valves remain closed
- The successive stages of the cardiac cycle are briefly described below
Atrial systole: The atria contract due to wave of contraction, stimulated by SA node. The blood is forced into the ventricles as the bicuspid and tricuspid valves are open. Beginning of ventricular systole: The ventricles begin to contraction, stimulated by the AV node. The bicuspid and tricuspid valve close immediately producing part of the first heart sound. Complete ventricular systole: When the ventricles complete their contraction, the blood flows into the pulmonary trunk and aorta as the semilunar valves open. Beginning of ventricular diastole: The ventricles relax and the semilunar valves are closed. This causes the second heart sound. Complete ventricular diastole: The tricuspid and bicuspid valves are open when the pressure in the ventricles falls and blood flows from the atria into the ventricles. Contraction of the heart does not cause this blood flow. It is due to the fact that this blood flows. It is due to the fact that the pressure within the relaxed ventricles is less than that in atria and veins.

HEART SOUNDS

- There are sounds produced during heart beat due to closure of valves
- Lubb (S) first sound, systolic sound) is the first heart sound which is dull, loud or low pitched, of long duration (0.16 and 0.19 seconds) and is produced due to closure of atrio ventricular valves (tricuspid and bicuspid valves)
- Dup (S, second sound, diastolic sound) is the second heart sound which is sharp high pitched, of shorted duration (0.1 sec) and is produced due to closer of semilunar valves at the base of great arteries. A pause or gap occurs between the second sound and the first sound of next cycle. It coincides with ventricular diastole.
- Incomplete closure of valves due to disease or other defect produces abnormal heart sound called murmur. Heat sounds are listened by means of instrument called stethoscope.

CARDIAC OUTPUT.

- The volume of blood pumped by each ventricle per minute is called the cardiac output
- It is determined by multiplying the heart rate with the volume of blood ejected by each ventricle during each beat, which is called the stroke volume. Cardiac output = Heart rate \times stroke volume = 72 beats /min \times 0.08 litre/ beat = 5.5 litres/min
- Cardiac index is the minute volume per sq.m. of body surface area. Its normal value is 3.3 litre/min/sq.m

REGULATION OF HEART BEAT.

- Neural Regulation:**
 The cardiac centre lies in the medulla oblongata of the brain. The cardiac centre is formed of cardio-inhibitor and cardio-accelerated parts. The former decreases the rate of heart beat and the latter accelerates it. The cardioinhibitor is connected with the heart through vagus nerve (it carries – parasympathetic nerve fibres) and cardio accelerator through sympathetic nerve fibres. Sensory fibres extended from the receptors present in the superior vena cava aorta and carotid sinuses to the cardiovascular centre in medulla oblongata. The impulses received from the aorta and carotid sinuses decreases the heart rate, whereas the impulses from Vena cava increases the heart rate.
- Hormonal regulation:**
 Adrenaline and noradrenaline hormones are secreted by the medulla of the adrenal glands. Noradrenaline accelerates the heart beat under normal conditions while adrenaline does this function at the time of emergency. These hormones directly influence the SA node. Thyroxine hormone secreted by thyroid glands increases oxidative metabolism of the body cells. This requires more oxygen and thus indirectly increases heart beat. Body temperature also affect the pacemaker. Just 1^oC rise in temperature increases with exercise to provide additional oxygen and food to muscles.

ELECTROCARDIOGRAM (ECG)

- ECG is graph record of the elastic current produced by the excitation of the cardiac muscles. The instrument used to record the changes in an electrocardiograph. Waller (1887) first recorded the electrocardiogram but Einthoven (1906) studied ECG in detail and got Nobel Prize. He is also considered “father of the electrocardiography”

- A normal ECG is composed of P waves, a QRS wave (complex) and a T wave. The letters are arbitrarily selected and do not stand for any particular words
- The P wave is a small upward wave that indicates the depolarization of the atria (atrial contraction). It is caused by the activation of SA node.
- The QRS wave (complex) begins after a fraction of second of the P wave. It begins as a small downward deflection (Q) and continues as large upright ® and triangular wave, ending as downward wave (S) at its base. It represents ventricular depolarization (ventricular contraction)
- The T wave is a dome-shaped which indicates ventricular repolarisation (ventricular relaxation)
- Each large square represents 0.2 second. Normal P-R interval is 0.12 to 0.2 second. Normal QRS complex duration is 0.12 second. Normal Q-T interval is 0.4 second.
- Enlargement of the P wave indicates enlargement of atria. During atherosclerotic heart diseases and rheumatic fever, the P-R interval is lengthened. This is due to the inflammation of atria and AV nose
- The enlarged Q and R waves indicate a myocardial infection (heart attack). The S-T segment is elevated in acute myocardial infection and depressed when the heart muscle receives insufficient oxygen.
- T wave is flat when the heart muscles receives insufficient oxygen as in atherosclerotic heart disease. It may be elevated when the body's potassium level is increased.
- When ECG of person to be recorded, four leads (metal electrodes) are attached in the arms and legs. It is done after leaning and putting special jelly, which improves electrical conduction. With the help of rubber suction cup, an additional electrode is placed on the chest. Now the electrocardiograph is switched on which detects and amplifies the electrical current of the heart and transmits to the recording pen. The latter draws a wavy line that is called deflection wave.
- The importance of ECG is that it gives accurate information about the heart. Therefore, ECG is of great diagnostic value in cardiac diseases.

BLOOD PRESSURE

- It is the pressure exerted by the flow of blood on the walls of arteries and measured as millimeters of mercury by the instrument is called sphygmanometer (Riva-Rocci). It has a high systolic value (normal 120 mmHg) and low diastolic value (normal 80 mmHg). The difference between two is called pulse pressure.
- Hypertension (hyperpiesis)
It is sustained rise in arterial blood pressure or high blood pressure with systolic more than 140 mmHg and diastolic more than 90mmHg. The reason is stiffening of arterial walls due to cholesterol walls, varicose veins, obesity, toxins, hormones, defective kidney etc. Hypertension caused by hormones is called hypertension. Other forms of hypertension are known as primary hypertension. It accounts to 90% of the cases.
- High blood pressure harms three vital organs-heart, brian and kidney. It makes heart to overwork due to which congestive heart disease develops quite early. A blood pressure of 220/120 mmHg may cause internal haemorrhage due to rupturing of some blood vessel.

Cerebral haemorrhage causes stroke or CVA. Damage to optic arteries leads to blindness while a similar damage to renal vessels causes nephritis. It leads to renal failure.

- Hypotension (Hypopiesis)

It is low blood pressure with systolic below 110 mmHg and diastolic below 70 mmHg Hypertension is caused by low metabolic rate, starvation, anaemia, chronic vasodilation of arterioles, lower pumping activity, valvular defects, nervous disorders, Addison's disease. There is an increase relationship between rate of heart beat and blood pressure. The phenomenon is called marey's law of heart

DOUBLE CIRCULATION

Double circulation is the passage of same blood twice in the heart through separate pathways for completing one cycle. It causes only 25% of the blood being oxygenated at one time. Double circulation consists of two parts, pulmonary circulation and systematic circulation.

- 1) Pulmonary circulation : The movement of blood between heart and lung is called pulmonary circulation. Deoxygenated blood from body enters right atrium. It is passed to right ventricale and then into pulmonary arch for sending to lungs for oxygenation. From lungs the oxygenated blood is brought into left atrium
- 2) Systematic circulation: This is movement of blood between heart and different parts of body except lungs. Oxygenataed blood is received by left atrium. It is passed to left ventricle which pumps it into aorata for supply to body parts including walls of heart. On deoxygenation the blood passes back into right atrium of heart through coronary sinus, inferior vena cava and superior vena cava. Purpose of systematic circulation is to transport O2 and nutrients to tissue and remove CO2 and nitrogenous waste from them.

ARTERIAL SYSTEM

- It comprises all the arteries coming out of heart and supplying blood to different parts of body. The heart gives out two main arterial vessels, pulmonary arch (from right ventricle) and aorta.
- Pulmonary arch carries deoxygenated blood. It divides into two pulmonary arteries one for each lung. Aorta carries oxygenated blood. It is swollen into aortic sinus at its origin. Aortic sinus gives out right and left coronary arteries to the heart. Aorta then produces a short and wide innominate on right side, a left common carotid and a left subclavian before bending down as dorsal aorta. Innominate or branchiocephalic forms a right common carotid and a right subclavian. Subclavian provide oxygenated blood to fore limbs, chest and spinal cord. Carotids supply oxygenated blood to neck, face, mouth, eyes, scalp and brain
- Dorsal aorta has two parts, thoracic and abdominal. Thoracic aorta gives out oesophageal (to oesophagus), phrenic (to diaphragm), branches to back and intercostals (to intercostal muscles) in thoracic cavity. Abdominal aorta supplies blood to visceral organs and lower extremities. It first gives out thick celiac artery with branches like hepatic (liver), gastric (stomach), splenic (spleen), duodenal (duodenum) and pancreatic (pancreas). Below coeliac, abdominal aorta gives out a superior mesenteric artery (small intestine), two superior renal (adrenal or supra-renal glands), two renals (kidneys), two genitalis and inferior (posterior) mesenteric artery (large intestine) and then divides into two iliacs (pelvic region and lower limbs)
- 4% of arterial blood passes into heart, 10% to liver, 8% to brain, 15% to digestive tract and the remaining to rest of the body.

VENOUS SYSTEM

- It comprises all the veins that bring blood to the heart. Venous system consists of pulmonary veins, coronary sinus, portal system and venae cavae. Pulmonary veins are four in number, two from each lung. They bring oxygenated blood to left atrium. Coronary sinus collects deoxygenated blood from all the walls of heart. It opens into right atrium. Superior vena cava is formed by two branchiocephalic veins each of which receives deoxygenated blood from a jugular vein (from head and neck), subclavian vein (upper limb) and internal thoracic vein (part of chest). Before opening into right atrium, superior vena cava receives a small accessory vein from oesophagus and intercostal area.
- Inferior vena cava is formed by the union of two common iliac veins (pelvis and lower limbs). While on its way to heart, it receives genital veins (gonads), lumbar veins (muscles of back), renal (liver) and phrenic veins (diaphragm). It then opens into right atrium.

PORTAL SYSTEM

- It is a system made of a portal vein and the capillary complex formed by it in an organ than the one of its origin. A portal vein is the vein which collects blood from one organ by a set of capillaries and distributes that blood into a second organ through another set of capillaries instead of sending blood into heart. There are three types of portal systems – hepatic, hypophysial and renal.
- Hepatic portal system : It occurs in all vertebrates and is meant for taking blood from digestive tract, pancreas and spleen into liver. The system has a large hepatic portal vein that is formed by four veins-splenic (spleen), inferior mesenteric (rectum and distal part of colon), superior mesenteric (small intestine, caecum and proximal part of colon) and gastroepiploic (from stomach and pancreas). Hepatic portal vein enters liver and breaks into capillaries. The system function as a short circuit for
 - (i) Removal of glucose, amino acids and other nutrients.
 - (ii) Deamination of extra amino acids and conversion of harmful ammonia into urea
 - (iii) Separation of toxic chemicals and their detoxification
 - (iv) Direct pouring of liver products into venous blood
- Hypophysial portal system : It is a minor portal system that occurs in higher vertebrates. The system consists of a single hypophysial portal vein. The portal vein is formed by capillaries in the hypothalamus. It passes into anterior lobe of pituitary glands and breaks up into capillaries there. Hypophysial portal system is meant for pouring hormones secreted by hypothalamus directly into anterior part of pituitary.
- Renal portal system: It occurs in lower vertebrates (fish and amphibians), reduced in reptiles and aves and is absent in mammals. It consists of renal portal veins that bring blood from posterior part of the body directly into kidneys for removal of waste products.

LYMPHATIC SYSTEM

It comprise lymph, lymphatic capillaries, lymphatic vessels, lymphatic nodes and lymphatic ducts.

LYMPH

Lymph, a colourless fluid is a part of tissue fluid, which in turn, is a part of blood plasma. So the composition of tissue fluid and lymph is same as that of blood plasma but it lacks RBCs and large plasma proteins. As compared to the tissue fluid, the lymph contains very small amount of nutrients and oxygen, but contains abundant carbon dioxide and other metabolic wastes. Amoeboid shaped white blood corpuscles may be present in the lymph.

LYMPHATIC CAPILLARIES

Lymphatic capillaries lie close to the blood capillaries but differ from them to extent that they end blindly. Moreover, they have extremely thin walls. They are composed of a single layer of endothelial cells. The lymphatic capillaries of intestine absorb the digested fats. They are milky in appearance and are, therefore, called the lacteals.

LYMPHATIC VESSEL

The lymphatic capillaries unite to form large lymphatic vessels. They are composed of an outer coat of fibrous tissue, middle coat of muscular tissue and an inner lining of endothelial cells. The lymphatic vessels have numerous valves.

LYMPH NODER

- These are small oval or bean shaped structures located along the length of lymphatic vessels. Lymph nodes are most numerous in the thoracic mediastinum on the posterior abdominal wall in the abdominal mesenteries and in the pelvis neck and proximal ends of the limbs.
- Lymphatic nodes perform the following main functions.
- Both B-lymphocytes and T-lymphocytes are produced here.
- Macrophages of lymph nodes remove bacteria, foreign material and cell debris from the lymph.
- B-lymphocytes change to plasma cells that produce antibodies against invading antigens, while T-lymphocytes attack cells that are 'foreign' to the host body.

THORACIC DUCT

The lymphatic vessels of left side unite to form a thoracic duct. This duct begins at the cisternal chili, which is a sac-dilation situated in the front of the first and second number vertebrae. The thoracic duct contains several valves. It discharges its lymph into the left subclavian vein.

RIGHT LYMPHATIC DUCT

The lymphatic vessel of the right side of the thorax, head and neck unite to form right lymphatic duct. It is about 1 cm in length. It discharges its lymph into the right subclavian vein.

LYMPH MOVEMENT

The lymph flows in lymphatic vessels very slowly. Forcing out of fluid from the blood capillaries sets up some pressure in the tissue fluid. This establishes a pressure gradient in the lymphatics, causing flow of lymph in the latter. Movements of viscera and contractions of the body muscles help considerably in squeezing the lymph along. The valves present in lymphatic vessels prevent its back flow. Movement of villi assist flow of lymph in the lacteals. Gravity helps in moving the lymph down the lymphatic vessels of head and neck.

FUNCTIONS OF LYMPH

The lymph or lymphatic system serves functions as:

- It drains excess tissue fluid from the extracellular spaces into the fluid.
- Some of fluid from the digestive tract is absorbed into the lymph. The lymphatic vessels store this fluid temporarily and release it gradually so that the kidney do not face a sudden pressure of urine excretion.

- It carries carbon dioxide and nitrogenous waste materials that diffuse into the tissue fluid to the blood.
- It takes lymphocytes and antibodies from lymphatic nodes to the blood.
- It transported fat that is digested and absorbed in the intestine to the blood in the form of chylomicron droplets.
- It destroys the invading microorganisms and foreign particles in the lymphatic nodes.
- It maintains quality and quantity of the blood by restoring the fluid and solute that leaves it.
- It brings plasma protein macromolecules synthesized in the liver cells and hormones produced in the endocrine glands to the blood.

SPLEEN

Spleen is the largest component of the lymphatic system. It is large (7-10 cm in diameter), bean-shaped, vascular, dark red organ located in the abdomen just below the diaphragm at the tail of the pancreas behind the stomach.

The spleen is composed of red pulp (reticular tissue rich in RBCs) having small patches of white pulp (lymphatic nodes) scattered in it. The red pulp is enclosed by a capsule of white fibrous tissue. The capsule sends trabeculae into the pulp and is surrounded by visceral peritoneum.

FUNCTIONS

- i) Destruction of worn-out red corpuscles
- ii) Reservoir of rd corpuscles
- iii) Formation of agranulocytes
- iv) Production of antibodies
- v) Storage of iron
- vi) Erythropoiesis
- vii) Disposal of foreign elements

THYMUS

Thymus is also a lymphatic organ. It lies in the upper chest near the neck. It is prominent in children but begins to degenerate in early childhood. It educates the lymphocytes in the foetus to distinguish cells from foreign cells.

TONSILS

Tonsils too are lymphatic tissues. They are located in the throat. They do not filter lymph. They are thought to protect against infection.

SOME COMMON CARDIOVASCULAR DEFFECTS

1. Arteriosclerosis:
Sclerosis and hardening of walls of generally smaller arteries and arterioles is called arteriosclerosis. The common cause is deposition of calcium in tunica media cholesterol may get

calcified. The walls of arteries become stiff and rigid. There is a loss of elasticity. The phenomenon is called hardening of arteries. Limb arteries are usually the first to undergo arteriosclerosis. Lesions develop at branch points. It ultimately leads to distal obstruction causing pain, numbness of extremities, peripheral oedema, cyanosis etc. rupturing of some vessels also occur. It forms blood clot and blocks the flow of blood.

2. Atherosclerosis:

It is wall thickening and narrowing of lumen of medium and large arteries. In atherosclerosis, yellowish plaques (atheromas) of cholesterol and other lipids are deposited within tunica intima and inner part of tunica media where smooth muscles abound. They are mostly caused by low density lipoproteins or LDL which can pass through endothelium. Plaques grow. The smooth muscles also proliferate probably caused by release of platelet derived growth factor (PDGF). This occurs due to roughness of inner arterial lining. Thickening of arterial wall reduces the lumen size. In extreme cases growth of plaques may completely block an artery. Atherosclerosis leads to hypertension, reduced blood supply to limbs and other organs resulting in their dysfunctioning. Atherosclerosis in coronary arteries results in reduced O₂ supply to heart walls causing angina, myocardial infarction or heart attack or stroke.

3. Coronary artery disease (CAD)

Coronary arteries undergo atherosclerosis. There is deposition of calcium, fat and fibrous tissue which results in narrowing of the arterial lumen. Flow of blood in the affected arteries is reduced. The cardiac muscles supplied by the affected arteries will begin to deteriorate. There is thoracic pain, nausea, perspiration and E.C.G changes. The defect can be treated through angioplasty (breaking of arterial blockage by balloon catheter) and bypass surgery.

4. Angina or Angina pectoris

It is recurrent, spasmodic suffocating thoracic (or heart) pain which often radiates to left arm. Angina is generally caused by deficient blood supply to heart muscles. It is precipitated by excitement or strenuous physical activity. Angina pectoris can occur in all types of individuals. Both men and women of any age. However, it is more common in middle aged and elderly persons. Reduced blood supply to myocardial muscles occurs either due to constriction or obstruction of blood vessels.

5. Heart Failure

It is the inability of heart to supply blood in adequate quantities to all parts of the body. Heart failure is a syndrome of ventricular dysfunction. The person suffering from heart failure has reduced exercise capacity. Health of different muscles of the body would also be affected. Heart failure should not be confused with heart attack (heart muscle damaged due to inadequate blood supply) or cardiac arrest in which case there is stoppage of heart beat.

6. Cardiomegaly : hypertrophy of heart. Inflammation of heart is carditis.

7. Cardiomyopathy : Noninflammatory disease of heart muscle.

8. Ischaemic heart: Heart with degenerate or defective components due to rheumatic disorder or fever in childhood.

9. Rheumatic heart : Heart with degenerate or defective components due to rheumatic disorder of fever in childhood.

1. 10. Embolus: Mass of clotted blood, other formed elements, fragments, air, calcium etc. coming from a larger blood vessel is forced into a smaller or narrow blood vessel resulting in its blockage and hence obstruction of blood circulation.
2. 11. Myocardial Infarction: Complication due to reduced blood supply to heart wall-pain, pallor, perspiration, nausea, ECG changes.
3. 12. Heart Burn (Pyrosis). Sensation of burning occurring in waves in oesophagus tending to rise upward towards neck often with reflex into mouth. It has nothing to do with heart.
4. 13. Varicose Veins: Unnatural permanently distended veins.
5. 14. Haematoma: Localised collection of usually clotted blood in a tissue or organ due to injury and rupturing of blood vessel.
